Abstract: The smelting of copper concentrate with a side submerged nozzle was modeled and simulated using the HSC SIM Chemistry Software version 6.12. To capture the physical-chemical behavior of the problem, the model is fed with industrial chemical analyzes corresponding to chalcopyrite concentrate used to determine the mineralogy. Heat losses were estimated at 12.05 GJ/h (3.35 MW). The model was based on simultaneous mass and heat balances using the progress of chemical reactions linked to software controllers to achieve the composition and temperature parameters of the white metal and slag.

Process analysis is performed by varying the air enrichment at different white metal grades. The most important results of the simulations are the required flows of blown air, industrial oxygen, flux and cold charge depending on the concentrate fed and its mineralogy. For a 28.74% copper concentrate that produces a 72% grade molten white metal, increasing the enrichment from 30 to 38% increases the cold charge flow from 4 to 27 t/h, increases the metal flow blank from 32 to 53 t/h, the flow of process gases decreases from 70,000 to 50,000 Nm³/h and the SO₂ concentration increases from 22 to 29%. An operation without enrichment will require the use of fuel to balance the thermal deficit.

Finally, the oxygen coefficient and the white metal law are directly proportional.

Keywords: Modeling, simulation, fusion, concentrate, controllers.

INTRODUCTION

Pyrometallurgical processes are widely used to treat copper concentrates due to their high production capacity due to the high kinetics developed at high temperatures, energy efficiency due to their autothermicity and the production of sulfuric acid from their gases.

Autothermicity requires maintaining

several operating parameters at their design values, which change due to operational variability, such as: flow of flux concentrate and circulating feed and their chemical and mineralogical compositions whose characterization is not periodic and therefore causes unforeseen events. in the operation. This makes the process unstable and must be monitored and controlled. Maintaining the temperature, composition and productivity of the final product obtained will depend on several possible operating scenarios.

The modeling and simulation of a melting furnace allows us to visualize what the optimal operating conditions will be according to the food and products to be obtained. Online, this would allow a prompt response to variations and return the process to steady state.

Oxygen enrichment directly affects the heat balance, since in the event of a thermal surplus it must decrease in such a way that the increase in the amount of nitrogen “cools the oven”, and vice versa in the event of a thermal deficit. Depending on the process and also on the materials, this can reach 80%. For fusion in the bath by submerged nozzle, it does not exceed 40%.

When the limit cannot be exceeded to balance a thermal surplus, it must be controlled by adding a cold load. On the other hand, in the event of a thermal deficit, an auxiliary fuel burner, coke addition or the like must be required.

The pyrometallurgical process for obtaining copper from sulfide ores using melting in the bath [1], can be described using Figure 1.

Once the ore is released and concentrated by crushing, grinding and flotation and later thickened, filtered and dried, it is fed to the smelting furnace that melts it and produces matte that goes to conversion, slag for copper recovery and gases that go to treatment to produce sulfuric acid. The matte is converted to blister copper in Converters which is fired

Fig. 2. Melting Furnace in the Bath by Lateral Submerged Nozzle

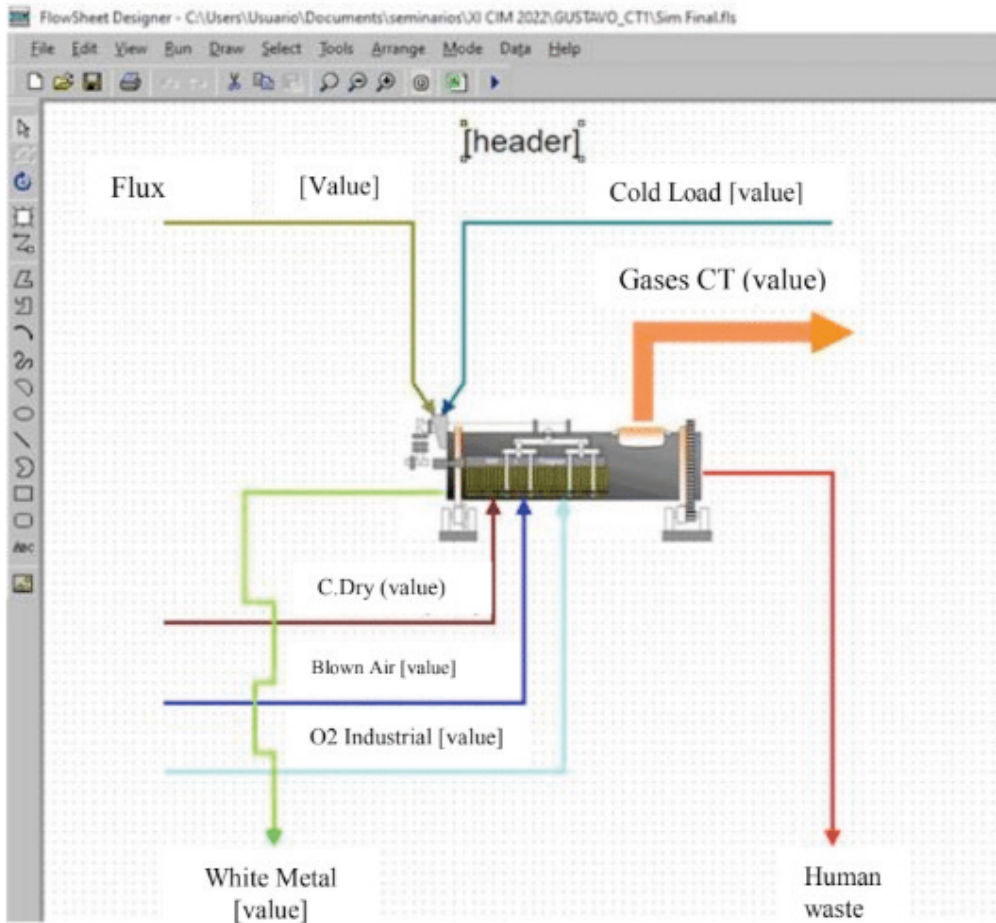

Figure 3. Furnace design and inlet and outlet flows of the process.

in anode furnaces that discharge the molten anode copper into molds to produce anodes.

In particular, the melting process in the bath [2] is described in the furnace presented in Figure 2.

Figure 2 shows that the concentrate enters mainly dry through four special nozzles located together with the enriched air injection nozzles (35 to 50) located laterally in the furnace mantle and towards the end of the cylinder head through which wet concentrate enters, cold and flux charge on the upper part of the mantle called gar-gun. This zone of concentrate/air injection presents a great turbulence where the concentrate that enters consumes heat to decompose and melt in the bath, this consumption is balanced by the generation of heat due to the oxidation of the FeS present. This produces a foamed emulsion of matte, slag and gases that are separated at the end of the furnace without nozzles and under the gas outlet. The matte sediments and settles at the bottom of the furnace from where it is discharged discontinuously through a hole and the slag, when separated, floats on the matte and is also discharged in the same way. Gases are continuously generated and emanated from the furnace mouth from where they are sent for cooling and cleaning to finally be conducted to the sulfuric acid production plant.

The operation of the Furnace consists of:

1. Continuous injection of dry concentrate and air
2. Continuous blowing of oxygen-enriched air
3. Continuous charge of flux and cold charge on the surface of the bath
4. Continuous extraction of process gases
5. Intermittent bleeding of mat and scum
6. Occasional recirculation of bushes

through the mouth.

The controls applied to maintain said stability are:

1. Slag temperature (approx. 1,240°C): controlled by adjusting the flow and oxygen enrichment of the supplied air.
2. Slag Composition: controlled by the flux feed flow to maintain 35% SiO₂ in the slag. This, added to good temperature control, yields a slag with 20 ± 4% Fe₃O₄.
3. Matte Composition: it is controlled by adjusting the ratio between the total oxygen flow fed and the dry concentrate flow fed, that is, the progress of oxidation of iron and sulfur of the matte

SIMULATION MODEL

The model developed is a simultaneous balance of mass and heat. A good closure of them allows the reactor to operate in a stable manner, that is to say, that the total flow of mass fed is equal to the total flow of mass of products and that the heat contributed by the oxidation reactions is equal to that necessary to decompose the minerals from the concentrate and melt the total load fed, also considering the heat losses from the furnace.

The simulation model was developed with the “Sim Flowsheet Simulation” module of the HSC Software - Chemistry v. 6.12 and complemented with the modules “Mineralogy Iterations” to determine the mineralogical composition from the chemical composition and “Heat Loss Calculator” to estimate heat losses [3]. The model in the “Sim Flowsheet Simulation” module is presented in Figure 3.

The model requires the following information in order to be executed:

1. Mineralogy of the concentrate
2. Composition of the cold load in percentage by mass
3. Composition of the flux in percentage

by mass

4. Composition of industrial oxygen in percentage by volumen
5. Raw material temperatura
6. Products temperatura
7. Heat losses of the Teniente Converter

The concentrate fed is presented in the following Table 1.

| Compound | CuFeS ₂ | Cu ₃ FeS ₄ | FeS ₂ | SiO ₂ | H ₂ O | Total |
|----------|--------------------|----------------------------------|------------------|------------------|------------------|-------|
| % weight | 70 | 7 | 15 | 7.8 | 0.2 | 100 |

Table 1. Mineralogical composition of the concentration:

The flux is composed of 90% SiO₂ and the remainder Fe₃O₄.

The cold charge is composed of 90% Cu₂S and the remainder Fe₃O₄.

Air has 21% oxygen and technical oxygen has 94%. The remainder in both streams is nitrogen.

The equations that the simulator will use to generate the outputs from the input data are called rulers and must represent the physico-chemistry of the process and the mechanism of decomposition, fusion and conversion. The model has 12 governing equations, which are presented in Table 2.

The above description of the governing equations and their progress is modeled in the software as presented in Figure 4 below.

To represent the process, the model, through its “distributions” tool [4], considers that 1% of the matte is trapped by the slag, distributing itself in it and that the matte contains 1% magnetite. On the other hand, it was considered that all the solids fed react completely, so the distribution of solids at the outlet is zero. Finally, the model vaporizes all the water that enters the reactor (Figure 5).

In order for the process to return to its operating parameters when faced with a system variation, the software counts

as a tool the “controllers” [4] so that the mathematical model iterates the values of the specified variables until the final response converges for an operational situation, particular. Controllers can run individually or simultaneously depending on convergence [5].

The model integrates 8 controllers that determine the required flows of flux, industrial oxygen, air and cold load required to obtain a matte and slag with specified characteristics, also closing the heat balance. The following Table 3 indicates the controllers used and the action they perform.

| Control | Action on |
|--------------------------------|---|
| White Metal Law | FeS oxidation reaction advance _(t) |
| Magnetite in the Slag | FeO oxidation reaction progress _(t) |
| Total Silica in Slag | Flux flow fed |
| FeO _(t) in the Slag | Advance reaction formation Fayalita |
| Total copper in the slag | Advance oxidation reaction Cu ₂ S _(t) |
| Total oxygen fed | Total Airflow Powered |
| Oxygen enrichment | industrial oxygen flow |
| Closing heat balance | cold load flow |

Table 3. Controls implemented in the model.

The controllers adjust to the model parameters that correspond to values of the variables set by the user and that correspond to the operation design. The model considers the product temperatures as parameters, setting the bath temperature at 1,250°C and the gas temperature at 1,300°C. The chemical quality specifications of the matte and slag are also parameters of the model.

PROCESS ANALYSIS PLANNING

The parameters of the model and variables for analysis are presented in Table 4.

As in the melting furnaces in the bath the enrichment cannot be high [6], the autothermicity is achieved operating with high-grade mattes, which are called white

| Description | Chemical reaction |
|--|---|
| Decomposition of chalcopyrite into the molten sulfides that make up the matte and the remaining sulfur oxidized with oxygen supplied to sulfur dioxide. | $2\text{CuFeS}_{2(s)} + \text{O}_{2(g)} = \text{Cu}_2\text{S}_{(l)} + 2\text{FeS}_{(l)} + \text{SO}_{2(g)}$ |
| Decomposition of the bornite into the molten sulfides that make up the matte and the remaining sulfur oxidized with oxygen supplied to sulfur dioxide. | $2\text{Cu}_5\text{FeS}_{4(s)} + \text{O}_{2(g)} = 5\text{Cu}_2\text{S}_{(l)} + 2\text{FeS}_{(l)} + \text{SO}_{2(g)}$ |
| Decomposition of pyrite into the molten iron sulfides that make up the matte and the remaining sulfur oxidized with oxygen supplied to sulfur dioxide. | $\text{FeS}_{2(s)} + \text{O}_{2(g)} = \text{FeS}_{(l)} + \text{SO}_{2(g)}$ |
| Decomposition of pyrite into the molten iron sulfide that makes up the matte and the remaining sulfur oxidized with oxygen supplied to sulfur dioxide. | $\text{FeS}_{2(s)} + \text{O}_{2(g)} = \text{FeS}_{(l)} + \text{SO}_{2(g)}$ |
| Decomposition of covelin in the molten copper sulfide that makes up the matte and the remaining sulfur oxidized with oxygen supplied to sulfur dioxide. | $2\text{CuS}_{(s)} + \text{O}_{2(g)} = \text{Cu}_2\text{S}_{(l)} + \text{SO}_{2(g)}$ |
| Fusion of the chalcocite present in the concentrate in the molten copper sulfide that makes up the matte | $\text{Cu}_2\text{S}_{(s)} = \text{Cu}_2\text{S}_{(l)}$ |
| Fusion of the magnetite present in the flux that goes on to compose the slag. | $\text{Fe}_3\text{O}_{4(s)} = \text{Fe}_3\text{O}_{4(l)}$ |
| Fusion of the silica present in the concentrate and flux that goes on to compose the slag. | $\text{SiO}_{2(s)} = \text{SiO}_{2(l)}$ |
| Vaporization of the water present in the concentrate to steam that makes up the process gases. | $\text{H}_2\text{O}_{(l)} = \text{H}_2\text{O}_{(g)}$ |
| Oxidation of the molten FeS in the matte to FeO, which is immiscible in the matte and starts to form the slag. This exothermic reaction is the main reason why the process is autothermal and no fuel is used. | $\text{FeS}_{(l)} + \frac{3}{2}\text{O}_{2(g)} = \text{FeO}_{(l)} + \text{SO}_{2(g)}$ |
| Oxidation of the FeO formed to magnetite in the slag. | $6\text{FeO}_{(l)} + \text{O}_{2(g)} = 2\text{Fe}_3\text{O}_{4(l)}$ |
| To avoid the formation of magnetite, a siliceous flux is provided to form fayalite that makes up the slag. | $2\text{FeO}_{(l)} + \text{SiO}_{2(g)} = \text{Fe}_2\text{SiO}_{4(l)}$ |
| Oxidation of the Cu ₂ S that makes up the kills to Cu ₂ O that goes on to form the slag. | $\text{Cu}_2\text{S}_{(l)} + \frac{3}{2}\text{O}_{2(g)} = \text{Cu}_2\text{O}_{(l)} + \text{SO}_{2(g)}$ |

Table 2. Description and governing equations.

The screenshot shows the 'Chemical Reactions Wizard' window with the 'Progress' tab selected. The main area contains a table with columns for 'No', 'Progress', 'Reactants', 'Products', 'Balance', 'H', and 'K'. The 'Reactants' and 'Products' columns are further divided into 'Separated with +'. The table lists 13 reactions, each with a percentage value in the 'Progress' column. The reactions are as follows:

| No | Progress | Reactants | Products | Balance | H | K |
|----|-----------|---------------------|---------------------------------|---------|---|---|
| 1 | 100 | 2 CuFeS2 + O2(g) | = Cu2S(l) + 2 FeS(l) + SO2(g) | | | |
| 2 | 100 | 2 Cu5FeS4 + O2(g) | = 5 Cu2S(l) + 2 FeS(l) + SO2(g) | | | |
| 3 | 100 | FeS2 + O2(g) | = FeS(l) + SO2(g) | | | |
| 4 | 100 | 2 CuS + O2(g) | = Cu2S(l) + SO2(g) | | | |
| 5 | 100 | Cu2S | = Cu2S(l) | | | |

Fig. 10. Results in the heat balance when operating without enrichment (white metal grade 72%).

metal, however, the above, its value varies from 72 to 76 % that is what will be analyzed through simulations, which must yield the following results.

The operation of the smelting furnace in the bath bases its enrichment on the increase in the flow of technical oxygen, which leads to a greater oxidation of FeS, and this, in turn, generates greater heat. This and other variables impact the operating parameters, therefore, the simulation through the “controllers” tool must return the process to its steady state, delivering new results such as the flow of white metal, slag and process gases.

RESULTS AND DISCUSSIONS

The effect on the industrial air/oxygen mixture required to produce a high-grade matte of 72% is shown below, given the increase in enrichment from 29 to 39%.

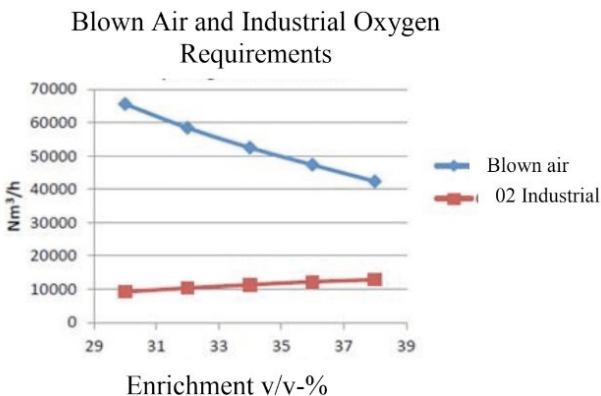

Fig. 6. Blowing air and industrial oxygen requirements versus % enrichment (white metal grade 72%).

From Figure 6 it can be inferred that as the enrichment increases from 30 to 38% the air flow decreases from 65,000 to 42,000 Nm³ while industrial oxygen increases from 9,000 to 12,000 Nm³. Correct situation since industrial oxygen is composed almost exclusively of oxygen. For example, for a volume of 100 Nm³ of air there are 21 Nm³ of oxygen and for 100 Nm³ of industrial oxygen there are 94 Nm³

of oxygen, therefore, a mixture with a greater flow of industrial oxygen than air flow will deliver a further enrichment.

The effect on flux feed and cold charge supply required to produce a 72% high grade matte is shown below, given the increase in enrichment from 29 to 39%.

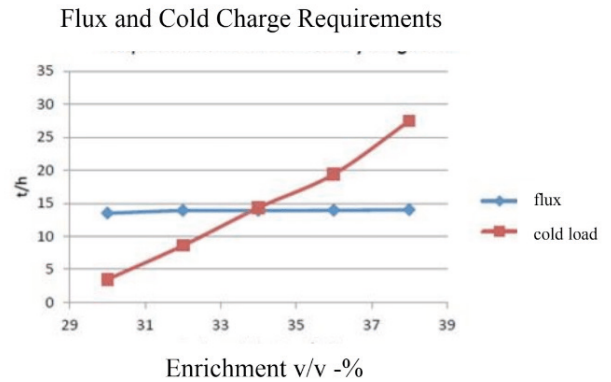

Fig. 7. Flux and cold charge requirements versus % enrichment (72% white metal grade).

The behavior shown in figure 7 indicates that as the enrichment increases from 30 to 38%, the flux demand remains practically constant at 14 t/h, this is due to the fact that the flux has effects on the silica content in the slag and its value is not appreciably related to the heat balance, however the cold load increases from 4 t/h to 27 t/h, which is coherent given that by increasing the enrichment less nitrogen is being blown into the reactor which it does not react and it simply takes sensible heat from the system, that is, it acts as a refrigerant, therefore, an increase in enrichment implies a greater quantity of oxygen and less nitrogen, therefore, the system presents a thermal surplus, part of it is released to the environment according to the losses of the equipment but the thermal surplus that still resides in the reactor must be balanced and this is achieved by consuming heat through low-temperature materials that consume sensible heat to reach the process temperature and reactions that are endothermic, as is the case of the components

of the cold load.

Below is the effect on white metal production and slag generation when a 72% white metal is produced, given the increase in enrichment from 29 to 39%.

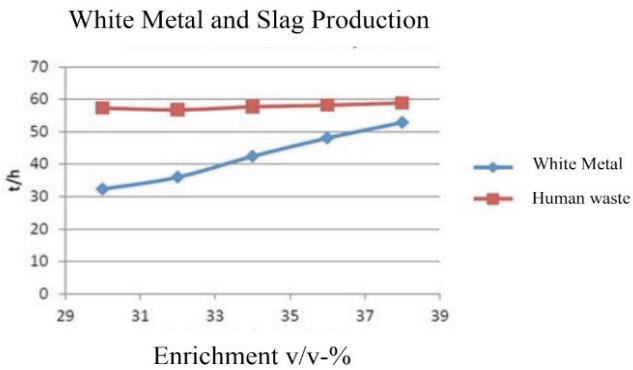

Fig. 8. Production of white metal and slag versus % enrichment (white metal grade 72%).

The behavior shown in figure 8 shows that as the enrichment increases from 30 to 38%, the slag production remains practically constant at 58 t/h but increasing and that of white metal increases significantly from 32 t/h to 53 t/h, this is due to the fact that as the enrichment increases, the cold load increases from 4 t/h to 27 t/h, which is made up of 90% Cu₂S and 10% Fe₃O₄, the amounts of which become part of the matte and slag, respectively. Therefore, the increase in white metal is due to the high percentage of Cu₂S in the cold charge used in the model.

Next, the effect on the volumetric flow of process gases and their concentration of sulfur dioxide in percentage is shown when a white metal of 72% is produced, given the increase in enrichment from 29 to 39%.

Output Gas Volume and SO₂ Concentration(g)

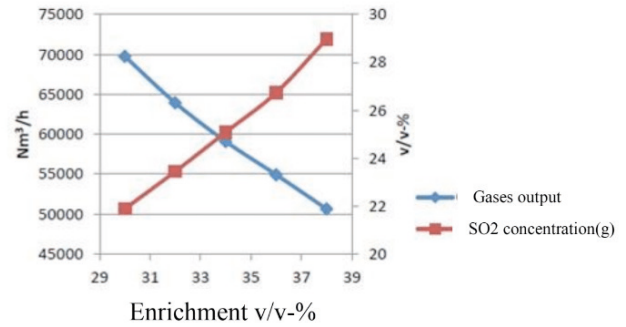

Fig. 9. Flue gas volumetric flow and % SO₂ versus % enrichment (72% white metal grade).

The behavior shown in figure 9 shows that as the enrichment increases from 30 to 38%, a lower volumetric flow of exhaust gases is generated and a higher concentration of sulfur dioxide in them, this is due to the fact that when enriching the volumetric flow of nitrogen, which is inert, is decreased and therefore its output value is equal to the input value. On the other hand, the volumetric flow of oxygen does not increase significantly before enrichment, therefore, the exhaust gases decrease from 70,000 Nm³/h to 50,000 Nm³/h, whose difference is attributable to the decrease in the volumetric flow of nitrogen, and as, the volumetric flow of sulfur dioxide is maintained, then the concentration of sulfur dioxide increases from 22% to 29% SO₂.

Next, the effect of operating without enrichment is shown, that is, the oxygen required to carry out the oxidation of the impurities is in a concentration of 21%, with the remaining 79% being nitrogen.

It can be seen that the heat balance does not close (Cell "J8"), and that the system presents a thermal deficit or is endothermic ($\Delta H > 0$), that is, the reactor requires heat to operate within the thermal parameters. This can be balanced by burning fossil fuel, preheating the feed streams, delivering sensible heat to the system, or another alternative would be to feed low grade molten matte from another

smelter.

The results for higher grade bushes (74 and 76%) are similar to the previous ones and their quantification is given by the execution of the simulation. For the oxygen coefficient index, it increases linearly from 266 to 281 Nm³ of O₂/ton of concentrate as the white metal grade increases from 72 to 76%, operating with an enrichment of 36%.

CONCLUSIONS

To produce a 72% matte, as the enrichment increases from 29 to 39%, the air flow decreases from 65,000 to 42,000 Nm³ while the industrial oxygen increases from 9,000 to 12,000 Nm³.

To produce a 72% matte as enrichment increases from 29 to 39%, the flux feed is a

constant 14 t/h, and the cold charge increases from 4 t/h to 27 t/h.

To produce a 72% matte as enrichment increases from 29 to 39%, slag generation is 58 t/h, and white metal increases from 32 t/h to 53 t/h.

To produce a 72% matte as enrichment increases from 29 to 39%, the volumetric flow of process gases decreases from 70,000 Nm³/h to 50,000 Nm³/h and the sulfur dioxide concentration increases from 22% to 29% of SO₂.

Without enrichment extra heat supply is required to close the balance.

Keeping the enrichment fixed at 36%, the oxygen coefficient increases linearly from 266 to 281 Nm³ O₂/ton of concentrate as the white metal grade increases from 72 to 76%.
